For comments and discussions I thank David Anthoff, Stefan Baumgärtner, Larry Karp, Per Krusell, Georg Müller-Fürstenberger, Agustín Pérez-Barahona, Rick van der Ploeg, David Popp, William Nordhaus, Tony Smith, Christian Traeger, the participants at the WCERE 2014 conference in Istanbul, the SURED 2014 conference in Ascona, the 5th International Meeting for Business and Management in Nice, and especially Reyer Gerlagh, Humberto Llavador and Gwenaél Piaser for extensive discussions and comments. I am not aware of any remaining errors.

Abstract

The results in this paper show that a policy maker who ignores regional data and instead relies on aggregated integrated assessment models will strongly underestimate the carbon price and thus the required climate policy. Using a stylized theoretical model we show that, under the mild and widely-accepted assumptions of asymmetric climate change impacts and declining marginal utility, an Aggregation Dilemma may arise that dwarfs most other policy-relevant aspects in the climate change cost-benefit analysis. Estimates based on the RICE model (Nordhaus and Boyer 2000) suggest that aggregation leads to around 26% higher total world emissions than those from a regional model. The backstop energy use would be zero in aggregated versions of the model, while it is roughly 1.3% of Gross World Product in the regionally-disaggregated models. Though the policy recommendations from fully aggregated models like the DICE model are always used as a benchmark for policy making, the results here suggest that this should be done with the reservations raised by the Aggregation Dilemma in mind.

Keywords: Aggregation Dilemma; aggregation; Integrated Assessment Models; climate policy.

JEL classification: Q54; Q58

1 Introduction

In this article we take a step towards answering the following question: Assume we had sufficient data and information on regional or country-specific feedbacks between economic growth and climate change. In this case, what would be the cost of ignoring this information and instead of using regional or country-level integrated assessment models to rely on an aggregated, global approach? In a similar spirit, should we push the development of disaggregated models or can we, for our policy analyses, continue to rely on their aggregated counterparts? To answer this question we present both a theoretical and an empirical investigation. In our theoretical part we use a stylized mathematical model that helps us in illustrating circumstances under which ignoring the regional data may turn out to lead to crucial differences in optimal policy prescriptions. In the empirical part we forward a quantification of the differences in optimal policies using regional and aggregated versions of the RICE model (Nordhaus and Yang 1996). The contribution of this article is to show that ignoring the regional information is by no means an innocent choice and leads to substantial divergences in the recommended climate change policies.

It is clear that we prefer to rely on highly aggregated models for a variety of reasons. While one may ideally wish to study heterogeneous agents at the smallest level, it may be infeasible due to data constraints (Orcutt et al. 1968) and complexity. There is ample measurement error out there, and often it is easier to predict the behavior of the aggregate than an individual. In addition, increasing complexity may itself lead to infeasible optimization problems, both in terms of time constraints and solvability. Another issue has been raised by Nordhaus and Sztorc (2013), who noted that an increasingly complex code for disaggregated integrated assessment models is much more likely to be error prone. Nevertheless, we have to be aware of the negative side effects of this aggregation, and these tend to matter more the larger the regional differences in the climate change impacts. We call this the ‘Aggregation Dilemma’. The results presented in this paper show that the Aggregation Dilemma can readily dwarf most other policy-relevant issues like discounting, risk aversion or climate sensitivity. We also show that these other commonly-addressed problems strongly interact with the Aggregation Dilemma. For example, we find that both a lower discount rate as prescribed by e.g. Stern (2007), and a faster decline in the marginal utility (i.e. a lower intertemporal elasticity of substitution) both worsen the Aggregation Dilemma. Though the policy recommendations from fully aggregated models like the DICE model (Nordhaus 1993, Nordhaus and Sztorc 2013) are always used as a benchmark for policy making, the results here suggest that this should be done with the reservations raised by the Aggregation Dilemma in mind.

The main assumptions underlying the results in this article are that climate change affects

agents asymmetrically, and that costs and benefits are evaluated using a utility function with declining marginal utility. In this case it is already well-known that the conditions under which a representative agent may exist are restrictive. However, the question is whether different levels of aggregation, e.g. at the world level, as is being done in the DICE model,¹ or the regional level, as is the case for the RICE model,² lead to different results. In addition, if the results are different, then the question is as to how quantitatively important are those differences. In case that we find significant differences in optimal policy from an aggregative model like the DICE one and from a more disaggregated one like the RICE model, then we have to ask ourselves whether the benefits of using a more aggregated model, like simplicity and data availability, necessarily outweigh the costs, namely the underestimation of carbon prices and climate policy.

There are other studies that have looked more specifically at different aspects of climate policy. Prominent examples are Tol (2002), who looked at risk aversion, inequality aversion, time discounting (Tol 1999), equity weighing within the social welfare function (Fankhauser et al. 1997), different types of social welfare function (d'Arge et al. 1982, Tol 2001), or the interaction between transfers and climate policy (Sandmo 2007, Anthoff 2011). An excellent overview can also be found in Botzen and van den Bergh (2014). Furthermore, in a series of articles Llavador, Roemer and Silvestre (2010, 2011a, 2011b, 2012) have shown the wide-ranging policy implications of moving away from the discounted utilitarian criterion towards more inclusive criteria of welfare or more egalitarian ones. All these issues are clearly important for policy making. Also, some of these strongly interact with the Aggregation Dilemma that we discuss in the following sections. As a result, these articles should be viewed as raising complementary issues that any policy maker needs to be aware of when evaluating climate policy. Nevertheless, it is important to keep in mind that in this article we only address the Aggregation Dilemma itself, and thus study the impact of ignoring the importance of asymmetries by (falsely) favoring more aggregative models. An article that raised a somewhat similar point to ours is Hassler and Krusell (2012). In that article, the authors develop a four region integrated assessment model and show that the optimal policy in a homogenous region world differs from the optimal policy in a heterogeneous region world from the individual perspective of a region. Thus, the authors look at a decentralized setting and study the result of regional heterogeneity, while we look at a global policy maker and more carefully investigate the implication of aggregation.

¹Other integrated assessment models at this level of aggregation are the ENTICE-BR (Popp 2006), DEMETER-1CCS (Gerlagh 2006) and MIND model (Edenhofer et al. 2005).

²Other integrated assessment models at this level of aggregation are the models FEEM-RICE (Bosetti et al. 2006a), FUND (Tol 1997), MERGE (Manne and Richels 2005), WITCH (Bosetti et al. 2006b), CETA-M (Peck and TJ 1999), GRAPE (Kurosawa 2004) or AIM/Dynamic Global Masui et al. (2006). For more information on these models the reader is referred to Stanton et al. (2009).

The plan of the paper is the following. In section 2 we discuss a simple analytical model in order to show that only few, well-accepted assumptions are necessary to induce the Aggregation Dilemma. We develop a general result that is able to point out two main issues: One, the optimal climate policy tends to be smaller in aggregative models compared to disaggregated ones. Two, under realistic assumptions the marginal willingness to undertake climate policy is infinite when policy is determined based on the disaggregated model. In contrast, an aggregated model would have a bounded marginal willingness to undertake climate action. In section 3 we provide an empirical estimate of the Aggregation Dilemma based on a minimally-modified RICE model. Section 4 concludes with some lessons one may wish to take away from this study.

2 A general result on the Aggregation Dilemma

In this theoretical section we want to frame the problem at hand within the basic features of the integrated assessment models in order to highlight as to what drives the Aggregation Dilemma. In order to do so, it is useful to frame the problem within the current climate policy debate. The predominant approach is to rely on models that combine economic and climate feedbacks, the so-called integrated assessment models. The class of models that is of particular interest here is the welfare maximizing one,³ with the well-known aggregate DICE and the regionally-disaggregated RICE models of Nordhaus and his co-authors (2010, 2013) as the front runners. The focus will be on what is called the optimal solution, thus the solution where a single policy maker finds the best possible outcome excluding additional policy targets (like the 2 °C target) or problems of cooperation. As such, by focusing on only the optimal solution and abstracting from additional policy-relevant targets, we are able to gain in clarity.

The original DICE model (Nordhaus 1993) and its currently latest version (Nordhaus and Sztorc 2013) are highly aggregated integrated assessment models. There are economic and climatic feedbacks, and a policy maker evaluates the optimal allocations that maximize utility subject to economic and climate feedback constraints. The world is modeled as one unit, with all individual consumption being aggregated, averaged across individuals, and then evaluated in a utility function. The matter would indeed be trivial and this model would be able to well-capture the best possible climate action if regional-specific differences in climate damages would be sufficiently small. In this case, the conditions for the existence of a representative agent would be fulfilled. A representative agent model is one where the aggregated action of all individuals can

³See the review Stanton et al. (2009) for other classes, like general equilibrium models or cost minimization ones.

be represented by the actions of one agent alone. However, simply aggregating across economic and climate constraints implies the existence of a representative agent only if all individuals are sufficiently similar.⁴ We want to draw attention to the limits of this modeling approach by showing important differences in the optimal allocations if climate impacts are not uniform across individuals, and thus the problem with the usage of ‘the average’.

Let us assume there exist N individuals⁵, each having a positive endowment of w in period 1 and of $(1 + g)w$ in period 2. We assume the growth rate g is bounded from below, with $g > -1$, however it is a non-vital component of the model that exists solely to please growth-oriented economists. In the initial period we assume that climate policy can be undertaken, while the second period is the impact period, in which agents potentially benefit from the climate action of the initial period. For simplicity, we shall here assume that all individuals are the same except that they face different impacts from climate change. The assumption that all individuals are the same is certainly not realistic and tilts the model in favor of an aggregative model. Nevertheless, we show that, even in this case, regional differences in climate change impacts are enough to induce substantial differences in optimal policies between disaggregated and aggregated models. Each individual will be affected by climate change that comes in proportion to period 1 wages, and each individual is affected differently. We can order individuals and the impact on them according to $\psi_i > 0$, $i = 1, \dots, N$, where $\psi_1 < \psi_2 < \dots < \psi_N$. Thus, individual 1 will see the weakest impact from climate change⁶, while individual N will be impacted the most, given by ψ_N . The average impact is given by $\bar{\psi} = \frac{1}{N} \sum_i \psi_i$.

Since the regional differences in climate impacts drive our subsequent results we have to provide evidence supporting this assumption, which we nevertheless believe to be a by now well-described empirical regularity. For example, substantial differences in local or regional impacts of climate change have been clearly shown in the contribution of Working Group II of the Fourth Assessment Report of the IPCC, see Parry et al. (2007). This report describes the various regional impacts of climatic changes. Among many other, these points stand out:

⁴See also Kirman (1992), who suggests that a representative agent framework is generally “unjustified and leads to conclusions which are usually misleading and often wrong.” (p.117) Further discussions are in Stanton et al. (2009) or Stanton (2011).

⁵When we talk about individuals we have any unit of disaggregation in mind, may it be regions, countries, counties or true individuals. For the same of simplicity we simply call these different levels of disaggregation ‘individuals’.

⁶One could also allow for a potentially positive impact, but would then have to re-write the model slightly. Thus we restrict ourselves, without loss of generality, to $\psi_i > 0$. For a model where climate policy has more the character of a transfer the reader is referred to an older working paper version of this article (Schumacher 2014). The difference to that previous model is that, in the current article, mitigation effort is not individual-specific but total mitigation effort has an impact on damages. Thus, the model here brings us closer to abatement or mitigation efforts in the standard sense, while in the previous model we were more closely dealing with adaptation efforts.

“By mid-century, annual average river runoff and water availability are projected to increase by 10-40% at high latitudes and in some wet tropical areas, and decrease by 10-30% over some dry regions at mid-latitudes and in the dry tropics.” In terms of flooding, “[t]he numbers affected will be largest in the mega-deltas of Asia and Africa while small islands are especially vulnerable.” Similarly, “[s]tudies in temperate areas have shown that climate change is projected to bring some benefits, such as fewer deaths from cold exposure. Overall it is expected that these benefits will be outweighed by the negative health effects of rising temperatures worldwide, especially in developing countries.” Again, “[c]limate change is expected to have some mixed effects, such as a decrease or increase in the range and transmission potential of malaria in Africa.” Finally, “[i]t is projected that crop yields could increase up to 20% in East and South-East Asia while they could decrease up to 30% in Central and South Asia by the mid-21st century.” This led the IPCC to one of their main conclusions: “Costs and benefits of climate change for industry, settlement and society will vary widely by location and scale. In the aggregate, however, net effects will tend to be more negative the larger the change in climate.” Thus, the IPCC clearly states that there are strong differences in local or regional impacts, with some potentially positive ones and other negative ones, while the overall, aggregate effect should be negative.

It should be emphasized that the potential importance of individual-specific climate impacts for policy decisions has been foreseen in the literature. This is the reason why e.g. Nordhaus and Yang (1996) developed a regionally-disaggregated model, the RICE model. When they introduced the first version of the RICE model, they noted that “[g]lobally aggregated models have the shortcoming of losing many of the interesting and important details of different regions.” Some of these interesting and important details are obviously issues related to cooperation across regions, but the one we shall concern ourselves here is the region-specific difference in the climate impacts.

We assume that all ψ_i 's are a function of the total abatement effort of period 1 individuals, such that $\psi_i(\sum_i A_i)$. We take it that the following conditions apply to all functions ψ_i .

A 1 *Functions $\psi_i(\sum_i A_i)$ follow $\psi_i(0) > 0$, $\psi'_i(\sum_i A_i) < 0$, $\psi''_i(\sum_i A_i) > 0$, $\psi_i(\infty) = 0$ and $\psi'_i(0) < \infty$.*

Thus, climate damages come as a share of income, and total abatement expenditure diminishes this impact at a decreasing rate. Climate damages tend to zero for very large sums of abatement expenditure, and the marginal benefit at zero abatement expenditure is finite. This last assumption is not vital but it helps to nicely carve out the point that climate policy may not be undertaken simply because it is extremely useful at the limit, but for the reasons that we shall discuss below.

We will furthermore work with the following assumption.

A 2 $\psi'_i(\sum_i A_i) = \psi'_j(\sum_i A_i), \forall i = 1, \dots, N \text{ and all } j = 1, \dots, N.$

While the previous assumptions should be standard and easily acceptable, Assumption 2 is a strong one. Clearly, it could potentially come from models that predict an equality between marginal abatement benefits and marginal abatement costs, which together with emission trading schemes eventually may induce equal marginal abatement benefits across individuals. However, there is clearly no need to be naïve about this assumption: It is unrealistic and only taken for the purpose of illustrating the potential extent of the Aggregation Dilemma in the most simplest mathematical framework. Readers may want to investigate the implication of weakening this assumption along various lines. However, especially with the subsequent Assumptions 3 and 4 in mind, it should be obvious that the general message of the Aggregation Dilemma stays unchanged.

Our approach then is as follows. We first introduce the policy maker's maximization problem assuming he has all the necessary data and information about all individuals and makes full use of it. For easy comparison with the integrated assessment literature we call this the *RICE case*. We then introduce the model where the policy maker ignores this information and instead models the world as consisting of only one individual, namely the average individual. This we dub the *DICE case*. Then we compare the different policies that arise from these models. For those readers unfamiliar with the RICE and the DICE models it must be emphasized that they are much more complicated models that are intended to be policy-relevant and thus sufficiently close representations of reality. We neither claim that our highly stylized model below is policy-relevant in a quantitative sense nor intend our theoretical model to be an approximation to the integrated assessment models. Nevertheless, the basic structures of the RICE and DICE models, in terms of aggregation in e.g. the DICE model, disaggregation in e.g. the RICE model, as well as the possibility to undertake a costly action now that benefits the future, are sufficiently close to these models below so that we believe we can take the liberty of borrowing their names for ease of comparison and discussing the Aggregation Dilemma qualitatively. In the next section we provide a quantitative estimate of the costs of aggregation.

The **RICE case** is given by

$$U\left(c_{1i}, \dots, c_{1N}, c_{2i}, \dots, c_{2N}\right) = \sum_i u(c_{1i}) + \sum_i u(c_{2i}), \quad (1)$$

which should be maximized subject to

$$w/N = c_{1i} + A_i, \quad (2)$$

$$c_{2i} = \left(1 + g - \psi_i \left(\sum_i A_i \right)\right) w/N, \quad (3)$$

which hold $\forall i = 1, \dots, N$. As suggested above, assuming all individuals to be identical and having the same incomes with the only differences being individual-specific climate impacts intuitively tilts the model towards favoring an aggregative approach.⁷ Consequently, if we observe differences between the aggregated model and this disaggregated one, then one should expect those differences to be even more important in models that take further differences between the individuals into account.

The first-order conditions in this case will be given by

$$-u'(c_{1i}) \leq \frac{w}{N} \sum_i u'(c_{2i}) \psi' \left(\sum_i A_i \right), \quad (4)$$

for all $i = 1, \dots, N$.

The **DICE case** is given by

$$U \left(\sum_i c_{1i}, \sum_i c_{2i} \right) = Nu \left(\frac{\sum_i c_{1i}}{N} \right) + Nu \left(\frac{\sum_i c_{2i}}{N} \right), \quad (5)$$

which should be maximized subject to

$$w/N = c_{1i} + A_i, \quad (6)$$

$$c_{2i} = \left(1 + g - \psi_i \left(\sum_i A_i \right)\right) w/N, \quad (7)$$

which hold $\forall i = 1, \dots, N$. Thus, the main differences between the RICE case and the DICE case is that the policy maker ignores regional asymmetries in the DICE case and instead simply averages consumption across all individuals.⁸ We shall show that it is precisely this averaging which leads to potentially drastic differences in optimal policies whenever we have differences

⁷A word on Negishi weights may be in order here since they tend to have an important standing in the integrated assessment literature. The equality of all functions but especially income can also be interpreted as implying that Negishi weights have been put in place. Hence, a policy would not be undertaken to equalize incomes across regions, e.g. in the form of wealth transfers, but solely in the interest of choosing the optimal climate policy.

⁸An alert reader may want to point out that the constraints (6) and (7) are not properly averaged yet. However, it can easily be shown that this model is fully equivalent to one where both constraints are evaluated at the averages.

in the climate impacts on individuals and decreasing marginal utility.

The first-order conditions will be given by

$$-u' \left(\frac{\sum_i c_{1i}}{N} \right) \leq u' \left(\frac{\sum_i c_{2i}}{N} \right) \frac{w}{N} \sum_i \psi'_i \left(\sum_i A_i \right), \quad (8)$$

for all $i = 1, \dots, N$.

If we now compare the two sets of first-order conditions from the DICE (eq. (8)) and from the RICE case (eq. (4)), then the main difference comes from the fact that in the DICE case we have only the second-period marginal utility of aggregated consumption, while in the RICE case we have the *sum* of all individual's second-period marginal utilities. We state the first result of this theoretical part in the following proposition.

Proposition 1 *Let A^d denote the optimal expenditure on mitigation in the DICE case, while A^r refers to the one in the RICE case. Then under Assumption 1 and 2 we find that*

$$\sum_i A_i^d < \sum_i A_i^r.$$

Proof of Proposition 1 *Proof by contradiction. From the first order conditions of the aggregated utility model we have $u'(c_{1i}) = u'(c_{1j})$, $\forall i, j$. Assume $\sum_i A_i^c = \sum_i A_i^u = \tilde{A}$. This would imply*

$$u' \left(\frac{\sum_i c_{2i}}{N} \right) \frac{w}{N} \sum_i \psi'_i \left(\sum_i A_i \right) = \frac{w}{N} \sum_i u'(c_{2i}) \psi' \left(\sum_i A_i \right).$$

Simplifying gives

$$Nu' \left(\frac{\sum_i c_{2i}}{N} \right) = \sum_i u'(c_{2i}).$$

However, since $u'(c)$ is a convex function then by Jensen's inequality the equality above is impossible. Instead, we know that for $\sum_i A_i^d = \sum_i A_i^r$ we obtain $Nu' \left(\frac{\sum_i c_{2i}}{N} \right) < \sum_i u'(c_{2i})$, which implies that $\sum_i A_i^d < \sum_i A_i^r$. ■

What Proposition 1 shows it that, despite everything else being equal, mitigation actions in the RICE case will be larger than in the DICE case as long as we have declining marginal utilities and asymmetric climate impacts.⁹ Quite clearly, if we assume either of these assumptions away,

⁹If A1 is not satisfied, then there are specific cases under which Proposition 1 does not hold. For example, if one region is rich but mitigation effects in that region have a strong marginal impact, then the sign may be reversed. However, what we suggest is that in case impoverishment is the driver of mitigation behavior, that means if climate

then both the DICE and the RICE cases lead to equivalent results. Nevertheless, the declining marginal utility is certainly one assumption that protrudes through the whole economic literature, while the asymmetry in the regional impacts of climate change are viewed as an empirical regularity.

One may wish to emphasize that this result may be weakened or strengthened depending on what additional differences between individuals are imposed. For example, there are differences in income between individuals, the growth rate tends to be larger for poorer individuals, utility functions may differ, and so on. It goes without saying that all these points will have an impact on the total mitigation efforts of the RICE and DICE case. Thus, it is necessary to evaluate empirically how relevant the difference between the RICE and DICE case really is. Before we tend to this in the next section, we will push the theoretical results on the Aggregation Dilemma somewhat further in order to show how easily it can be taken to the extreme.

2.1 Two extreme yet realistic cases

Let us take the analysis above yet one step further and introduce the following two assumptions.

A 3 We assume that $\exists k \in \mathbb{Z}(N)$, s.th. $\forall i \geq k, \psi_i(0) \geq 1 + g$.

This implies that, in case of zero mitigation action, agent k , and any agent more strongly impacted than agent k , will lose all wealth in period 2.

A 4 Assume that $\exists h \in \mathbb{Z}(N)$, s.th. $\forall i \geq h, \psi_i(\sum_i w_i) \geq 1 + g$.

This assumption states that, even if all agents spend all their income on mitigation, all agents ranked after agent h will still lose all their wealth in period two. Thus, the difference between A3 and A4 is that in the first assumption we take it that there exists at least one agent that will lose everything if no mitigation effort is undertaken, while the second assumption implies that there exists at least one agent that will lose everything even if as much mitigation effort is being done as is physically possible.

Proposition 2 Assuming A3 implies that the marginal benefit to adaptation expenditure is

$$\lim_{\sum_i A_i \rightarrow 0} \sum_i u'(c_{2i}) \psi'_i(\sum_i A_i) = \infty,$$

change is strongly impacting one region or agent, then this may fully drive mitigation actions in the aggregated utility case.

while

$$\lim_{\sum_i A_i \rightarrow 0} u' \left(\frac{\sum_i c_{2i}}{N} \right) \sum_i \psi'_i \left(\sum_i A_i \right) < \infty.$$

Assuming A4 implies that

$$\forall A_i \in [0, w), \sum_i u'(c_{2i}) \psi'_i \left(\sum_i A_i \right) = \infty,$$

while

$$\forall A_i \in [0, w), u' \left(\frac{\sum_i c_{2i}}{N} \right) \sum_i \psi'_i \left(\sum_i A_i \right) < \infty.$$

Proof of Proposition 2 Follows directly from A3 and A4. ■

We may thus conclude that, as long as there is at least one agent who is fully impoverished by climate change, then this agent will drive the marginal benefit of climate action in the RICE case to infinity. In contrast, in the DICE case, this does not happen since climate impacts get averaged away.

Furthermore, assume there exists at least one agent who is so strongly impacted by climate change that he would lose everything even if all agents were to spend all income on mitigation effort. As a result, the willingness to undertake climate action would be infinite at every level of adaptation expenditure. This last result seems controversial in the sense that transfers could eliminate it. Allowing for transfers in a regional public good model, Sandmo (2007) and Anthoff (2011) have shown that this may reduce climate action. For example, if A4 holds, then one can very well imagine that transfers could be a cheaper means of achieving equality in marginal utilities than climate action. However, this conclusion would also depend on whether we account for uncertainty or fat tails in climate change impacts, which may affect utility directly. Both additional issues can easily tip the scale towards maximal climate action again.

3 Empirical estimate of the Aggregation Dilemma

As suggested above, the mathematical result suggests that under mild assumptions, the RICE case may potentially lead to an infinite marginal willingness to undertake climate policy. This stands in stark contrast to the DICE case, which may, under the same assumption, recommend no climate action at all. Hence, the policy implications of the Aggregation Dilemma may be substantial and dwarf most other aspects of climate policy that have been deemed important in the recent studies. It is, thus, certainly of interest to investigate the empirical relevance of the

theoretical result and to investigate as to how important this result may be in reality. Clearly, if this turns out to be sizable, it is reasonable to believe that aggregated integrated assessment models (like the DICE model) may prescribe a far too conservative climate policy than could be necessary. In order to provide an empirically-relevant estimate of the Aggregation Dilemma, we minimally adapt the code for the RICE-99 model that Professor Nordhaus kindly provides (Nordhaus and Boyer 2000).

First off, it is clear that the RICE model by Nordhaus, or any currently available integrated assessment model, is already a model which is aggregated at a certain level. For the sake of argument we shall simply suggest that we have good data and information about the regions of the world as defined in the RICE model, and take this as our starting point.

We study three different scenarios. The first scenario is based upon the RICE case, which is defined as

$$U^r = \sum_T \sum_N 10 * R(T)P(T, N) \log \left(\frac{C(T, N)}{P(T, N)} \right). \quad (9)$$

Utility U^r is defined as the discounted ($R(T)$) sum of population-adjusted ($P(T, N)$) felicities, which are give by the logarithm of time and region-specific per capita consumption ($C(T, N)/P(T, N)$). This is equivalent to the utility function used in the RICE-99 model, except that we neglect Negishi weights. We neglect these as we would like to obtain a solution that corresponds as closely as possible to the RICE case as defined in the theoretical part above, and furthermore we want to avoid the ethical connotation underlying Negishi weights.¹⁰ However, as all regional integrated assessment models rely on Negishi weighting, it seems reasonable to nevertheless study the impact of these in comparison to the unweighted RICE case and the DICE case. Thus, we also study the potential differences that may arise through the use of Negishi weights. Our second scenarios is therefore defined by

$$U^{rN} = \sum_T \sum_N 10 * R(T)P(T, N)W(N) \log \left(\frac{C(T, N)}{P(T, N)} \right). \quad (10)$$

where U^{rN} stands for the utility functional in the RICE case with Negishi weights ($W(N)$), and it corresponds fully to the social welfare function used in the RICE-99 model. Negishi weights are used to stop incentives for income re-distribution due to initial wealth differences and thereby instead help to focus the policy maker's attention on taking care of the climate externality. Thus, if there are differences in the optimal climate policy between the unweighted and the Negishi weighted simulation results, then these should be due to climate policy being used as a means of

¹⁰For discussions on the Negishi weights the reader is referred to Stanton (2011).

reducing income differences in the unweighted RICE case.

The third scenario is the DICE case. For this we aggregate consumption in utility and then average it across individuals, just like in the original DICE model. Hence, we denote the DICE case as

$$U^d = \sum_t 10 * R(T)P(T) \log \left(\sum_N \frac{C(T, N)}{P(T)} \right). \quad (11)$$

One issue here is that this does not yet correspond to a fully aggregated model since the production functions differ across regions. Thus, a policy maker may wish to invest more or less in climate policy depending on how this affects the production functions. Hence, in our final scenario we take the DICE case but, in addition, we aggregate and average the production functions, capital and labor across regions. In the RICE-99 model the production functions $F_i(\cdot)$ are region-specific, depend on total factor productivity A_{it} , capital K_{it} , labor L_{it} , carbon input E_{it} , the use of backstop energy B_{it} and are reduced by a climate impact feedback that depends on the level of temperature T_t . Thus, they are given by

$$F_{it}(K_{it}, L_{it}, E_{it}, B_{it}, T_t) = \frac{A_{it}K_{it}^\gamma L_{it}^{1-\gamma-\alpha_{it}}(E_{it} + B_{it})^{\alpha_{it}} - p_{it}E_{it} - q_i B_{it}}{1 + \mu_i T_t + \nu_i T_t^2} \quad (12)$$

We then define the aggregate, average production function by aggregating and averaging across regions, such that for all region-specific parameters $x_{it} = \{A_{it}, K_{it}, L_{it}, E_{it}, B_{it}, \alpha_{it}, p_{it}, q_i, \mu_i, \nu_i\}$ we define the regional average as $\bar{x}_t = \frac{1}{N} \sum_i^N x_{it}$. Consequently, a policy maker who ignores region-specific differences thus averages across regions and then aggregates production, such that total world production will be given by NF_t , where the inputs and parameters in this production function are the world averages. Our four scenarios are then summarized as follows.

Model	Utility	Production
RICE	U^r	F_{it}
RICE-N	U^{rN}	F_{it}
DICE	U^d	F_{it}
DICE-A	U^d	F_t

We present the simulations based on a policy maker's perspective who searches for the optimal solution with the choice variables in this model being region-specific carbon emissions, the use of backstop energy, and per capita consumption. The simulation results are given in Figure 1.¹¹

¹¹In fact, the results in the latest version of Nordhaus' RICE model (Nordhaus 2010) conform very closely to

In the DICE case, total world emissions are up to 26% higher than in the RICE case, and up to 16% higher compared to the RICE-N case. Aggregating fully, and thus not only ignoring regional differences in consumption but also in production, leads to emissions in the DICE-A case which are initially much larger (20%) compared to the RICE case (and 13% in the RICE-N case), with a difference that decreases slightly towards the middle of the century and then increases again. Overall, the stock of CO₂ is initially the largest in the DICE-A case, then it is overtaken after roughly 60 years by the atmospheric CO₂ of the DICE case. Nevertheless, both levels of CO₂ are always optimally higher in the aggregated cases than in the disaggregated ones, with the RICE case having the lowest level. One reason for the eventually lower emissions in the fully aggregated DICE-A case compared to the utility-aggregated DICE case is that the initially very high emissions in the DICE-A case may already be leading to forced emission reductions after 30 years.

Furthermore, the policy maker would use no backstop energy if he were to rely on either the DICE case or the DICE-A case for policy evaluation. Consequently, even in this fully calibrated models, the aggregated integrated assessment models average the climate damages away and lead to the least climate action. This stands in contrast to a policy maker's use of backstop energy in both the RICE and the RICE-N case, where the model without Negishi weights optimally allocates a maximum of 1.2% of the Gross World Product to the backstop use, while the model with Negishi weight allocates a maximum of 0.3%. In the RICE case, the total amount of backstop energy used is roughly 7.5 times larger than in the RICE-N case, the one with Negishi weights. Overall, the Negishi weights tip the scale towards to 'needs' of the richer regions, in the sense that they reduce the incentives for capital transfers from the rich to the poor. Conclusively, whatever one believes to be the correctly-specified regional model, i.e. the one with or the one without Negishi weights, in both cases the results clearly show that ignoring regional differences leads to substantial changes in the prescribed optimal climate policy.

We can, therefore, conclude that a policy maker who ignores regional data always underestimates the necessary policy interventions and the carbon price. Consequently, the Aggregation Dilemma holds true not only for the theoretical model as shown above, but also for a fully calibrated integrated assessment model which is widely used for policy considerations.

Sensitivity analysis of these results, available from the author, to generally discussed parameters in the integrated assessment literature, namely the discount rate and the intertempo-

ours' (the RICE-N case). The only difference in the optimal path of CO₂ emissions is that in the new version the emissions increase slightly faster and consequently reduce slightly quicker than our RICE-N case, which itself is equivalent to the model in Nordhaus and Boyer (2000). The reason why we did not use the latest RICE version is because it has not been yet provided in GAMS code.

ral elasticity of substitution, suggests that a higher discount rate reduces the difference in both the total world emissions and the use of the backstop energy between the DICE and RICE cases. The Aggregation Dilemma should, therefore, become more important under a low discount rate as prescribed by e.g. Stern (2007). In contrast, a lower intertemporal elasticity of substitution changes the results of the DICE case only marginally, while we observe large changes in the RICE cases. The use of the backstop energy is significantly higher, and total emission are much lower in the RICE cases if the intertemporal elasticity of substitution decreases. This result comes about since a lower elasticity of substitution places more weight on the worse off. Overall, the current results add to the previous studies investigating the sensitivity of climate policy recommendations to widely-discussed parameters in the literature (see e.g. Stern 2007, Nordhaus 2007, Weitzman 2007), like the discount rate or the curvature of the utility function, in the sense that they show that under different levels of aggregation in the social welfare functions the importance of these parameters increases or declines. Thus, there is considerable interaction between these widely-discussed parameters and the Aggregation Dilemma.

4 Conclusion

In this article we have shown that a policy maker, who - for whatever reason - chooses to ignore regional differences in climate impacts in favor of a more aggregative approach will seriously underestimate the optimal policy interventions. This result relies on two mild and widely-accepted assumptions, namely asymmetric climate change impacts and declining marginal utility. We show how, in theory, a disaggregated model can easily generate an infinite willingness to undertake mitigation efforts, while its aggregated counterpart may prescribe limited or even zero climate action. This we call the Aggregation Dilemma, and we show how it dwarfs most other policy-relevant aspects in the climate change cost-benefit analysis.

We provide empirically-relevant estimates of the Aggregation Dilemma using a marginally modified RICE-99 model. Estimates of the potential errors of aggregation suggest that a higher level of aggregation leads to a much lower investment in climate policy, with total world emissions in the aggregated models being up to 26% higher than in the disaggregated ones. Furthermore, the policy maker would use no backstop energy if he were to rely on the aggregated models for policy evaluation. This stands in contrast to his use of backstop energy in the disaggregated models, where he would optimally allocate a maximum of 1.2% of the Gross World Product to the backstop use. Though the policy recommendations from fully aggregated models like the DICE model are always used as a benchmark for policy making, the results here suggest that this

should be done with the reservations raised by the Aggregation Dilemma in mind.

Our results emphasize the need to move away from the highly aggregated integrated assessment models towards ones that are able to properly take region-specific differences in climate impacts into account. Thus, we here stress the importance of further developing the regional integrated assessment models.

In future research it would be useful to push these results on the Aggregation Dilemma a step further. For example, it would be important to know by how much the Aggregation Dilemma worsens if one moves from the regional RICE model to one with smaller units of analysis, e.g. to country or county levels. In this respect, Krusell and Smith (2009) are currently undertaking a research project with an extremely large number of regions (19,000 in total). In a much less ambitious project we are extending the RICE model to a country-level one. As our results here have shown, since sufficient data on smaller units exists, then given the asymmetric climate impacts across the world it is vital to not neglect this data and fully incorporate the heterogeneities in the integrated assessment modelling so as not to underestimate the true costs of climate impacts across the world.
